Load the packages, as always

```
library(here) # manage file paths
library(socviz) # data and some useful functions
library(tidyverse) # your friend and mine
library(gapminder) # inescapable

library(DBI) # DBMS interface layer
library(duckdb) # Local database server
```

"Big" Data

What we're talking about

Mostly in this case, datasets that are nominally larger than your laptop's memory.

There are other more specific uses, and truly huge data is beyond the scope of the course. But we can look at methods for working with data that's "big" for all practical purposes.

When we're working with data in the social sciences the basic case is a single table that we're going to do something with, like run a regression or make a plot.

```

But the bigger a dataset gets, the more we have to think about whether we really want (or even can have) all of it in memory all the time.

In addition, much of what we want to do with a specific dataset will involve actually acting on some relatively small subset of it.

```

Efficiently storing and querying really large quantities of data is the realm of the database and of Structured Query Languages.

As with everything in information technology there is a long and interesting story about various efforts to come up with a good theory of data storage and retrieval, and efficient algorithms for it. If you are interested, watch e.g. this lecture from a DBMS course from about twelve minutes in.

Where's the database?

Local or remote?

On disk or in memory?

The important thing from the database admin's point of view is that the data is stored *efficiently*, that we have a means of *querying* it, and those queries rely on some search-and-retrieval method that's *really fast*.

There's no free lunch. We want storage methods to be efficient and queries to be fast because the datasets are gonna be gigantic, and accessing them will take time.

Database layouts

A real database is usually not a single giant table. Instead it is more like a list of tables that are partially connected through keys shared between tables. Those keys are indexed and the tables are stored in a tree-like way that makes searching much faster than just going down each row and looking for matches.

From a social science perspective, putting things in different tables might be thought of a matter of logically organizing entities at different *units of observation*. Querying tables is a matter of assembling tables ad hoc at various *units of analysis*.

Again, in social science terms, the redundancies are annoying in part because they apply to different levels or units of observation. From a Database point of view they are also bad because they allow the possibility of a variety of errors or anomalies when updating the table, and they make things really inefficient for search and querying.

A hierarchical set of rules and criteria for ensuring the integrity of data stored across multiple tables and for reducing redundancy in data storage.

Tries to elminate various sources of error — so-called Insertion, Update, and Deletion anomalies — particularly ones that will pollute, damage, or corrupt things beyond the specific change.

Redundancy and error are minimized by breaking the database up into a series of linked or related tables. Hence the term "relational database"

Normal Forms

ONF: No duplicate rows!

1NF: Using row order to convey information is not allowed; Mixing data types in the same column is not allowed; No table without a primary key is not allowed. Primary keys can be defined by more than one column though. No "repeating groups".

2NF: Each non-key attribute must depend on the entire primary key

3NF: Every non-key attribute should depend wholly and only on the key.

Think of these rules in connection with ideas about "tidy data" that we've already covered.

Talking to databases

The main idea

Ultimately, we query databases with SQL. There are several varieties, because there are a variety of database systems and each has their own wrinkles and quirks.

We try to *abstract away* from some of those quirk by using a DBI (DataBase Interface) layer, which is a generic set of commands for talking to some database. It's analogous to an API.

We also need to use a package for the DBMS we're talking to. It translates DBI instructions into the specific dialect the DBMS speaks.

Talking to databases

Some databases are small, and some are far away.

Client-server databases are like websites, serving up responses to queries. The database lives on a machine somewhere in the building, or on campus or whatever.

Cloud DBMSs are like this, too, except the database lives on a machine in someone else's building.

In-process DBMSs live and run on your laptop. We'll use one of these, duckdb for examples here.

Talking to databases

We need to open a *connection* to a database before talking to it. Conventionally this is called con.

Once connected, we ask it questions. Either we use functions or packages designed to translate our R / dplyr syntax into SQL, or we use functions to pass SQL queries on directly.

We try to minimize the amount of time we are actually making the database do a lot of work.

The key thing is that when working with databases our queries are *lazy* — they don't actually do anything on the whole database unless its strictly necessary or they're explicitly told to.

Example: flights

The nice example

Where everything is lovely and clean. Thanks to Grant McDermott for the following example.

duckdb and DBI

```
# library(DBI)
con ← dbConnect(duckdb::duckdb(), path = ":memory:")
```

Here we open a connection to an in-memory duckdb database. It's empty. We're going to populate it with data from nycflights.

duckdb and DBI

```
copy_to(
  dest = con,
  df = nycflights13::flights,
  name = "flights",
  temporary = FALSE,
  indexes = list(
    c("year", "month", "day"),
    "carrier",
    "tailnum",
    "dest"
  )
  )
}
```

Remember, keys and indexes are what make databases fast.

Make a lazy tibble from it

This says "go to con and get the 'flights' table in it, and pretend it's a tibble called flights_db.

```
flights_db ← tbl(con, "flights")
flights_db
           table<flights> [?? x 19]
# Source:

# i 1,191 more rows
```

Now it exists for realsies.

Joins

Database systems will have more than one table. We query and join them. The idea is that getting the DBMS to do this will be way faster and more memory-efficient than trying to get dplyr to do it.

Joins

```
## Copy over the "planes" dataset to the same "con" DuckDB connection.
copy_to(
    dest = con,
    df = nycflights13::planes,
    name = "planes",
    temporary = FALSE,
    indexes = "tailnum"
    )

## List tables in our "con" database connection (i.e. now "flights" and "planes")
dbListTables(con)

[1] "flights" "planes"
```

See what we did there? It's like con the database connection has a list of tables in it.

Reference from dplyr

planes_db ← tbl(con, 'planes')

Joins

```
# Still not done for realsies!

Close your connection!

dbDisconnect(con)

Example: ARCOS Opioids data

This one is messier

I'm not going to do it on the slides. We'll try to process a pretty big data file on a machine of modest proportions.
